#### Abstract

Given a sequence $S=s_{1} s_{2} \ldots s_{n}$ of integers smaller than $r=O($ polylog $(n))$, we show how $S$ can be represented using $n H_{0}(S)+o(n)$ bits, so that we can know any $s_{q}$, as well as answer rank and select queries on $S$, in constant time. $H_{0}(S)$ is the zero-order empirical entropy of $S$ and $n H_{0}(S)$ provides an information-theoretic lower bound to the bit storage of any sequence $S$ via a fixed encoding of its symbols. This extends previous results on binary sequences, and improves previous

#### Abstract

A subset of the results presented in this article appeared in the Proceedings of the 11 th Symposium on String Processing and Information Retrieval (SPIRE), pp. 150-160, 2004. This work was partially supported by MIUR under Italy-Israel FIRB Grant "Pattern Discovery Algorithms in Discrete Structures, with Applications to Bioinformatics," by MIUR under PRIN Grant "MainStream", by Yahoo! Research grant on "Data compression and indexing in hierarchical memories, by the Academy of Finland under Grant 108219, and by the Millennium Nucleus Center for Web Research, Grant P04-067-F, Mideplan, Chile. results on general sequences where those queries are answered in $O(\log r)$ time. For larger $r$, we can still represent $S$ in $n H_{0}(S)+o(n \log r)$ bits and answer queries in $O(\log r / \log \log n)$ time.

Another contribution of this article is to show how to combine our compressed representation of integer sequences with a compression boosting technique to design compressed full-text indexes that scale well with the size of the input alphabet $\Sigma$. Specifically, we design a variant of the FM-index that indexes a string $T[1, n]$ within $n H_{k}(T)+o(n)$ bits of storage, where $H_{k}(T)$ is the $k$ th-order empirical entropy of $T$. This space bound holds simultaneously for all $k \leq \alpha \log _{|\Sigma|} n$, constant $0<\alpha<1$, and $|\Sigma|=O(\operatorname{polylog}(n))$. This index counts the occurrences of an arbitrary pattern $P[1, p]$ as a substring of $T$ in $O(p)$ time; it locates each pattern occurrence in $O\left(\log ^{1+\varepsilon} n\right)$ time for any constant $0<\varepsilon<1$; and reports a text substring of length $\ell$ in $O\left(\ell+\log ^{1+\varepsilon} n\right)$ time.

Compared to all previous works, our index is the first that removes the alphabet-size dependance from all query times, in particular, counting time is linear in the pattern length. Still, our index uses essentially the same space of the $k$ th-order entropy of the text $T$, which is the best space obtained in previous work. We can also handle larger alphabets of size $|\Sigma|=O\left(n^{\beta}\right)$, for any $0<\beta<1$, by paying $o(n \log |\Sigma|)$ extra space and multiplying all query times by $O(\log |\Sigma| / \log \log n)$.
Categories and Subject Descriptors: E. 1 [Data]: Data Structures—Arrays; trees; E. 4 [Data]: Coding and Information Theory-Data compaction and compression; F.2.2 [Analysis of Algorithms and Problem Complexity]: Nonnumerical Algorithms and Problems-Pattern matching; sorting and searching; H.3.1 [Information Storage and Retrieval]: Content Analysis and Indexing—Indexing methods; H.3.3 [Information Storage and Retrieval]: Information Search and Retrieval—Search process; I.7.2 [Document and Text Processing]: Document Preparation-Index generation
General Terms: Algorithms, Theory
Additional Key Words and Phrases: Text indexing, text compression, entropy, Burrows-Wheeler transform, compression boosting, wavelet tree, rank and select

## 1. Introduction

Recent years have witnessed an increasing interest in succinct data structures. Their aim is to represent the data using as little space as possible, while efficiently answering queries on the represented data. Several results exist on the representation of sequences [Jacobson 1989; Munro 1996; Clark 1996; Pagh 1999; Raman et al. 2002], trees [Munro and Raman 1998; Geary et al. 2004; Ferragina et al. 2005], graphs [Munro and Raman 1998], permutations [Munro et al. 2003], and texts [Grossi and Vitter 2006; Ferragina and Manzini 2005; Sadakane 2003; Navarro 2004; Grossi et al. 2003], to name a few.

One of the most basic structures, which lies at the heart of the representation of more complex ones, is binary sequences with rank and select queries. Given a binary sequence $S=s_{1} s_{2} \ldots s_{n}$, we denote by $\operatorname{Rank}_{c}(S, q)$ the number of times that bit $c$ appears in $S[1, q]=s_{1} s_{2} \ldots s_{q}$, and by $\operatorname{Select}_{c}(S, q)$ the position in $S$ of the $q$ th occurrence of bit $c$. The best current results [Pagh 1999; Raman et al. 2002] answer these queries in constant time, retrieve any $s_{q}$ in constant time, and occupy $n H_{0}(S)+o(n)$ bits of storage, where $H_{0}(S)$ is the zero-order empirical entropy of $S$. This space bound includes that for representing $S$ itself, so the binary sequence is being represented in compressed form yet allows these queries to be answered optimally.

For the general case of sequences over an arbitrary alphabet of size $r$, the only known result is the one in Grossi et al. [2003], which still achieves $n H_{0}(S)+$ $o(n \log r)$ space occupancy. The data structure in Grossi et al. [2003] is the elegant
wavelet tree, taking $O(\log r)$ time to answer $\operatorname{Rank}_{c}(S, q)$ and $\operatorname{Select}_{c}(S, q)$ queries, and to retrieve any character $s_{q}$.

Our first contribution is a new compressed representation for general sequences which uses $n H_{0}(S)+o(n)$ bits of space and answers the aforementioned queries in constant time. This generalizes previous results on binary sequences [Raman et al. 2002] and improves the existing result on general sequences [Grossi et al. 2003]. Our result holds when the alphabet size is polylogarithmic in sequence length, that is, $r=$ $O($ polylog $(n))$. For larger values of $r$, we can represent $S$ using $n H_{0}(S)+o(n \log r)$ bits of space and answer all previous queries in $O(\log r / \log \log n)$ time.

General sequences can be regarded, of course, as texts over an alphabet $\Sigma$. The difference lies on the types of queries that are of interest for texts. A full-text index is a data structure built over a text string $T[1, n]$ that supports the efficient search for arbitrary patterns as substrings of the indexed text. A full-text index is called compressed if its space occupancy is bounded by $\lambda n H_{k}(T)+o(n \log |\Sigma|)$ bits for some $k \geq 0$, where $\lambda$ is a constant and $H_{k}(T)$ is the $k$ th-order entropy of $T$ (see Section 4.1). If such an index also encapsulates the text without requiring its explicit storage, then it is called a compressed self-index. Note that a self-index must, in addition to its search functionality, permit the display of any text substring, as the text is not separately available.

Recently, there has been a good deal of attention to compressed full-text indexes because of their obvious applications in text databases. The most succinct selfindex to-date [Grossi et al. 2003] occupies $n H_{k}(T)+O\left(n \log \log n / \log _{|\Sigma|} n\right)$ bits for a fixed $k \leq \alpha \log _{|\Sigma|} n$ and constant $0<\alpha<1$. It can count the number of occurrences of a pattern $P[1, p]$ in $O(p \log |\Sigma|+\operatorname{polylog}(n))$ time, and can locate each such occurrence in $O\left(\log |\Sigma| \log ^{2} n / \log \log n\right)$ time. To display a text substring of length $\ell$, it takes the locate time plus $O(\ell \log |\Sigma|)$.

Our second contribution (which builds on the first) is a new compressed selfindex that uses $n H_{k}(T)+o(n)$ bits for any $k \leq \alpha \log _{|\Sigma|} n$ and for alphabets of size $|\Sigma|=O(\operatorname{poly} \log (n))$. Our index improves upon that in Grossi et al. [2003] by removing from the query times the dependence on alphabet size and polylogarithmic terms. More precisely: Counting takes $O(p)$ time, locating an occurrence takes $O\left(\log ^{1+\varepsilon} n\right)$ time for any constant $\varepsilon>0$, and displaying a length- $\ell$ text substring takes the time for occurrence-locating plus $O(\ell)$. For alphabets larger than $O$ (polylog$(n)$ ) (and up to $O\left(n^{\beta}\right)$ for $0<\beta<1$ ), our space requirement becomes $n H_{k}(T)+o(n \log |\Sigma|)$ bits and our query times grow by a multiplicative factor $O(\log |\Sigma| / \log \log n)$.

The rest of the article is organized as follows. Section 2 explains our contributions in more detail and relates them to the current literature. Section 3 presents our new representation for general sequences, while Section 4 deploys such a sequence representation to design our new compressed self-index. Finally, Section 5 discusses conclusions and future directions of interesting research.

## 2. Our Contribution in Context

2.1. Succinct Sequence Representations. The first results on binary sequences [Jacobson 1989; Munro 1996; Clark 1996] achieved constant time on rank and select queries by using $n+o(n)$ bits. In those schemes, $n$ bits are used by $S$ itself and $o(n)$ additional bits are needed by the auxiliary data structures that support the Rank ${ }_{c}$ and Select ${ }_{c}$ queries. Further refinements [Pagh 1999; Raman et al. 2002]
achieved constant time on the same queries by using a compressed representation of $S$, requiring $n H_{0}(S)+o(n)$ bits overall (i.e., for $S$ and the auxiliary data structures). These solutions also support the constant-time retrieval of any bit $s_{q}$, given $q$.

The case of general sequences, whose symbols are drawn from the range $[1, r]$, has received less attention. The only existing proposal is the wavelet tree [Grossi et al. 2003], a powerful and elegant data structure that allows reducing rank and select operations over general sequences to rank and select operations over binary (compressed) sequences. By using the results in Pagh [1999] and Raman et al. [2002] for binary sequence representations, the wavelet tree represents $S$ in $n H_{0}(S)+o(n \log r)$ bits and answers $s_{q}$, $\operatorname{Rank}_{c}(S, q)$, and $\operatorname{Select}_{c}(S, q)$ queries in $O(\log r)$ time.

In this article we generalize the result on binary sequences [Pagh 1999; Raman et al. 2002] to sequences of integers in the range [ $1, r$ ], and obtain an improved result. The main challenge in this generalization is to generate short descriptions for pieces of the sequence, which can be computed in constant time and used to index into tables containing partial precomputed queries. This is significantly more complex than for binary sequences. We obtain a compressed sequence representation using $n H_{0}(S)+O\left((r n \log \log n) / \log _{r} n\right)$ bits which answers queries $s_{q}$, $\operatorname{Rank}_{c}(S, q)$, and $\operatorname{Select}_{c}(S, q)$ in constant time.

This first result is interesting only for small $r=o(\log n / \log \log n)$, as otherwise the term $O\left((r n \log \log n) / \log _{r} n\right)$ of the space complexity is $\Omega(n \log r)$. We then use this sequence representation as a basic block within a generalized wavelet tree to obtain better results. In fact, the original wavelet tree [Grossi et al. 2003] is a binary tree whose nodes contain binary sequences representing the original (general) sequence restricted to a subset of its symbols. In this article we consider a $h$-ary generalization of the wavelet tree that, in turn, requires efficient storage into its nodes of integer sequences from the range $[1, h]$. By setting $h=O\left(\log ^{\delta} n\right)$ with $\delta<1$, and using our previous sequence representation to store the wavelet-tree nodes, we obtain a representation for $S$ that uses $n H_{0}(S)+o(n)$ bits and (optimal) constant query time for any $r=O($ poly $\log (n))$. In other words, queries answered in logarithmic time with binary wavelet trees [Grossi et al. 2003] are now answered in constant time, within the same asymptotic space occupancy. For larger alphabets, we can still obtain $o(n \log r)$ extra space over the $n H_{0}(S)$ term and $O(\log r / \log \log n)$ query time, again improving upon binary wavelet trees by a sublogarithmic factor.

Note that there are even better results for binary sequences [Raman et al. 2002], which we have not generalized. For example, it is possible to represent a sequence with $m$ bits, set taking $n H_{0}(S)+o(m)+O(\log \log n)$ bits of space and constant query time for some limited queries. This is better than the result we have focused on when $m$ is much smaller than $n$.
2.2. Compressed Full-Text Indexes. Classical full-text indexes, namely suffix trees and suffix arrays [Crochemore and Rytter 1994; Manber and Myers 1993; Gonnet et al. 1992], are neither succinct nor self-indexes: They both occupy $\Theta(n \log n)$ bits, plus $O(n \log |\Sigma|)$ bits to represent the indexed text.

The FM-index [Ferragina and Manzini 2005] has been the first self-index in the literature to achieve a space occupancy proportional to the $k$ th-order entropy of $T[1, n]$. Precisely, the FM-index occupies at most $5 n H_{k}(T)+o(n)$ bits of storage, and allows one to count the number of occurrences of a pattern $P[1, p]$ within $T$ in $O(p)$ time. Each such occurrence can be located in $O\left(\log ^{1+\varepsilon} n\right)$ time, where $\varepsilon>0$
is an arbitrary constant chosen when the index is built. The FM-index can display any text substring of length $\ell$ in $O\left(\ell+\log ^{1+\varepsilon} n\right)$ time. The design of the FM-index is based upon the relationship between the Burrows-Wheeler compression algorithm [Burrows and Wheeler 1994] and the suffix array data structure [Manber and Myers 1993; Gonnet et al. 1992]. It is therefore a sort of compressed suffix array that takes advantage of the compressibility of the indexed text in order to achieve space occupancy related to the information-theoretic minimum. Indeed, design of the FM-index does not depend on the parameter $k$, whereas its space bound holds simultaneously for any fixed $k$. These remarkable theoretical properties have been validated by experimental results [Ferragina and Manzini 2001; Hon et al. 2004] and applications [Healy et al. 2003; Sadakane and Shibuya 2001].

The aforementioned time and space bounds for the FM-index have been obtained by assuming that the size of the input alphabet is a constant. Hidden in the big-O notation there is an exponential dependence on alphabet size in the space bound, and a linear dependence on alphabet size in the time bounds. More specifically, the time to locate an occurrence is $O\left(|\Sigma| \log ^{1+\varepsilon} n\right)$ and that to display a text substring is $O\left(\left(\ell+\log ^{1+\varepsilon} n\right)|\Sigma|\right)$. In practical implementations of the FM-index [Ferragina and Manzini 2001] these dependencies have been removed at the expense of a penalty factor (usually $O(\log n)$ ) that multiplies all query times, including that for counting.

We point out that the FM-index concept is more general than the implementation associated with its initial proposals [Ferragina and Manzini 2005, 2001]. For the sake of presentation, let us denote now by $T^{b w t}$ the permutation of the text $T$ given by the Burrows-Wheeler transform [Burrows and Wheeler 1994] (see Section 4.2). Assume we implement the computation of $\operatorname{Rank}_{c}\left(T^{b w t}, q\right)$ and the retrieval of $T^{b w t}[q]$ in time $t_{r n k}$ and $t_{r e t}$, respectively, using $O(N)$ space (where the parameter $N$ is discussed to follow). The general FM-index concept gives us immediately a succinct self-index that requires $O\left(N+n / \log ^{\varepsilon} n\right)$ space, counts the pattern occurrences in $O\left(p t_{r n k}\right)$ time, locates any such occurrence in $O\left(\left(t_{r n k}+t_{r e t}\right) \log ^{1+\varepsilon} n\right)$, and displays any text substring of length $\ell$ in $O\left(\left(t_{r n k}+t_{r e t}\right)\left(\ell+\log ^{1+\varepsilon} n\right)\right)$ time (here and in the rest of this section, $\varepsilon$ is a positive parameter chosen when the index is built). To-date, several implementations of the FM-index concept exist:
(1) the original [Ferragina and Manzini 2005], with $t_{r n k}=O(1)$ and $t_{r e t}=O(|\Sigma|)$, where $N=5 n H_{k}(T)+o(n)$ contains an exponential dependence on $|\Sigma|$ in the $o(n)$ term;
(2) the one obtained by using the binary wavelet tree [Grossi et al. 2003] to represent $T^{b w t}$ and to implement the required functions. This yields $t_{r n k}=t_{r e t}=$ $O(\log |\Sigma|)$, so counting time deteriorates but locating and displaying times improve. The space occupancy becomes $N=n H_{0}(T)+o(n \log |\Sigma|)$, which depends only mildly on $|\Sigma|$ but has a main term significantly worse than in the original implementation (since here $H_{0}(T)$ occurs in place of $H_{k}(T)$ ). Some variants providing $t_{r n k}=t_{\text {ret }}=O\left(H_{0}(T)\right)$ on average, and $O(\log |\Sigma|)$ in the worst case, have also been proposed [Mäkinen and Navarro 2004b];
(3) a variant of the compressed suffix array (CSA) introduced by Sadakane [2002]. Although the CSA was originally conceived as completely different from the FM-index, this specific variant is actually an implementation of the FM-index concept. It represents $T^{b w t}$ via $|\Sigma|$ binary sequences $T_{c}^{b w t}$, each indicating the occurrences of a different character in $T^{b w t}$. Those sequences are represented
with existing techniques [Pagh 1999], so that $\operatorname{Rank}_{c}\left(T^{b w t}, q\right)=\operatorname{Rank}_{1}\left(T_{c}^{b w t}, q\right)$ can be answered in constant time. This yields $t_{r n k}=O(1)$ and $t_{r e t}=O(|\Sigma|)$ as in the original implementation. The space occupancy is $N=n H_{0}(T)+O(n)$. The scheme works for $|\Sigma|=O(\operatorname{polylog}(n))$;
(4) that obtained by Huffman-compressing $T^{b w t}$ and then representing the resulting binary sequence with the techniques in Munro [1996]. This yields $t_{r n k}=t_{r e t}=$ $O\left(H_{0}(T)\right)$ on average and $O(\log |\Sigma|)$ in the worst case. The space occupancy is $N=2 n\left(H_{0}(T)+O(1)\right)(1+o(1))$ [Grabowski et al. 2006]; and
(5) the one obtained by compressing via run-length encoding the sequence $T^{b w t}$ [Mäkinen and Navarro 2005, 2004b]. This approach obtains either $t_{r n k}=O(1)$ and $t_{\text {ret }}=O(|\Sigma|)$ if $|\Sigma|=O(\operatorname{polylog}(n))$ or $t_{\text {rnk }}=t_{\text {ret }}=O(\log |\Sigma|)$ for larger alphabets. The space occupancy is $N=n H_{k}(T) \log |\Sigma|+O(n)$ bits. Notice that this is the only alternative to the original FM-index with space occupancy related to the $k$ th-order entropy (although it shows a linear dependence on $n$ but a milder dependence on $|\Sigma|$ ).

We note that by directly applying our new sequence representation on $T^{b w t}$, we immediately obtain $t_{r n k}=t_{\text {ret }}=O(1)$ time and $N=n H_{0}(T)+o(n)$, which supersedes all the alternatives whose space requirement is proportional to the zero-order entropy of $T$ (i.e., the preceding items 2,3 , and 4 ), as long as $|\Sigma|=O(\operatorname{polylog}(n))$. In this article we improve this by making a further step that turns $H_{0}(T)$ into $H_{k}(T)$ in the previous space bound. Precisely, our main result is an implementation of the FM-index concept with $t_{r n k}=t_{r e t}=O(1)$ time and $N=n H_{k}(T)+o(n)$, for a reasonable range of values of $k$ (see the following). Except for the limitation that $|\Sigma|=O(\operatorname{poly} \log (n))$, this implementation supersedes all existing implementations of the FM-index concept, thus can be regarded as the ultimate implementation of the FM-index. To obtain this result, we combine our sequence representation with the compression boosting technique introduced in Ferragina et al. [2005]. Compression boosting partitions the Burrows-Wheeler transformed text into contiguous areas in order to maximize the overall compression achievable with zero-order compressors used over each area. Then we use our new sequence representation in each area. The resulting structure is thus simple. It indexes a string $T[1, n]$ drawn from an alphabet $\Sigma$, with $|\Sigma|=O($ polylog $(n))$, using $n H_{k}(T)+O\left(n / \log ^{\varepsilon} n\right)$ bits. The data structure does not depend on the parameter $k$ and the space bound holds simultaneously for all $k \leq \alpha \log _{|\Sigma|} n$ and constant $0<\alpha<1$. With our index, counting the occurrences of an arbitrary pattern $P[1, p]$ as a substring of $T$ takes $O(p)$ time (i.e., no alphabet dependence). Locating each pattern occurrence takes $O\left(\log ^{1+\varepsilon} n\right)$. Displaying a text substring of length $\ell$ takes $O\left(\ell+\log ^{1+\varepsilon} n\right)$ time.

If the size of the alphabet is larger than polylogarithmic, that is, $|\Sigma|=O\left(n^{\beta}\right)$ with $\beta<1$, our data structure uses $n H_{k}(T)+o(n \log |\Sigma|)$ space and the query times are multiplied by a factor $O(\log |\Sigma| / \log \log n)$. Note that although the space occupancy can now be $\Omega(n)$, it is still less than the size of the uncompressed text. Moreover, in terms of query time our index is faster than most FM-index implementations. As an alternative, if space is more important than query speed, we can use a simplified version of our index which uses binary wavelet trees instead of our new integer sequences representation. For any alphabet size, the space occupancy of this latter index is bounded by $n H_{k}(T)+O(\log |\Sigma|(n \log \log n / \log n))$ bits for any $k \leq$

$\alpha \log _{|\Sigma|} n$, and $0<\alpha<1$. The index takes $O(p \log |\Sigma|)$ time to count the pattern occurrences, and $O\left(\log |\Sigma|\left(\ell+\log ^{2} n / \log \log n\right)\right)$ time to locate and display a substring of length $\ell$.

There exist several other compressed full-text indexes not based on the FMindex concept [Ferragina and Manzini 2005; Grossi and Vitter 2006; Sadakane 2003; Navarro 2004; Grossi et al. 2003; Foschini et al. 2006; Mäkinen et al. 2004; Mäkinen and Navarro 2004a]. Among them, the data structure with the smallest space occupancy is described in Grossi et al. [2003, Thms. 4.2 and 5.2], and uses $n H_{k}(T)+O(\log |\Sigma|(n \log \log n / \log n))$ bits of storage for a fixed $k \leq \alpha \log _{|\Sigma|} n$ with $0<\alpha<1$ (the parameter $k$ must be chosen when the index is built). The index in Grossi et al. [2003] takes $O(p \log |\Sigma|+\operatorname{polylog}(n))$ time to count the pattern occurrences and $O\left(\log |\Sigma|\left(\ell+\log ^{2} n / \log \log n\right)\right)$ time to locate and display a substring of length $\ell$. Note that for alphabets of polylogarithmic size our index is faster in both queries at the cost of a small increase in the big-O terms of the space occupancy. Note also that for any alphabet size our simplified data structure takes the same space as the index in Grossi et al. [2003], but is faster in counting the occurrences and takes the same time in reporting and displaying them.

Finally, we point out that the structure in Grossi et al. [2003] uses binary wavelet trees to compactly represent sequences. By replacing binary wavelet trees with the sequence representation described in this article, we can remove the $O(\log |\Sigma|)$ factors from their query times.

To summarize, our index has asymptotically the smallest-known space occupancy and processes all queries faster than the data structure in Grossi et al. [2003], which is the only other compressed index known to-date with essentially $n H_{k}(T)$ space occupancy. Table I summarizes our contribution.

## 3. Compressed Representation of Sequences

Let $S=s_{1} s_{2} \ldots s_{n}$ be a sequence of $n$ integers in the range [1, $r$ ], called symbols from now on. In this section we face the problem of supporting Rank and Select queries on $S$. The query $\operatorname{Rank}_{c}(S, q)$ returns the number of times that symbol $c \in[1, r]$ appears in $S[1, q]=s_{1} s_{2} \ldots s_{q}$. The query $\operatorname{Select}_{c}(S, q)$ returns the position in $S$ of the $q$ th occurrence of symbol $c \in[1, r]$. Our aim is to represent $S$ in compressed form, and hence we need to support also the retrieval of any $S[q]=s_{q}$.

We measure the size of the compressed representation of $S$ as a function of its zero-order empirical entropy $H_{0}(S)=-\sum_{c}\left(n_{c} / n\right) \log \left(n_{c} / n\right)$, where $n_{c}$ is the number of occurrences of symbol $c$ in $S, n=\sum_{c} n_{c}=|S|$, and all logarithms are taken to the base 2 (with $0 \log 0=0$ ). Notice that $n H_{0}(S)$ is an informationtheoretic lower bound to the compressibility of $S$ when we use a fixed codeword for each of its symbols.
3.1. Representing Sequences of Small Integers. In this section we describe the first data structure which represents $S$ in $n H_{0}(S)+$ $O\left((r n \log \log n) / \log _{r} n\right)$ bits, and answers $S[q], \operatorname{Rank}_{c}(S, q)$, and $\operatorname{Select}_{c}(S, q)$ queries in constant time. For the construction of the data structure we only need $2 \leq r \leq \sqrt{n}$, but the data structure is interesting only for $r=o(\log n / \log \log n)$, since otherwise the space occupancy will exceed the space $\Omega(n \log r)$ used by the standard uncompressed representation. We first focus on $S[q]$ and $\operatorname{Rank}_{c}(S, q)$ queries, and address the $\operatorname{Select}_{c}(S, q)$ query later.
3.1.1. Structure. We divide $S$ into blocks of size $u=\left\lfloor\frac{1}{2} \log _{r} n\right\rfloor$. Consider a block where each symbol $c$ appears $N^{c}$ times, so $N^{1}+N^{2}+\ldots+N^{r}=u$. We say that tuple $\left(N^{1}, N^{2}, \ldots, N^{r}\right)$ is the symbol composition of the block. Using this notation, we define the following sequences of values indexed by block number $i=1, \ldots,\lceil n / u\rceil$ :
$-S_{i}=S[u(i-1)+1 \ldots u i]$ is the sequence of symbols forming the $i$ th block of $S$;
-for each symbol $c \in[1, r], N_{i}^{c}=\operatorname{Rank}_{c}\left(S_{i}, u\right)$ is the number of occurrences of $c$ in $S_{i}$;
$-L_{i}=\left[\log \binom{u}{N_{i}^{1}, \ldots, N_{i}^{r}}\right]$ is the number of bits necessary to encode all possible sequences of $u$ symbols in $[1, r]$ that share the symbol composition $\left(N_{i}^{1}, \ldots, N_{i}^{r}\right)$ of block $S_{i}$;
$-I_{i}$ is the identifier of block $S_{i}$ among all sequences having its symbol composition ( $N_{i}^{1}, \ldots, N_{i}^{r}$ ). Specifically, $I_{i}$ consists of $L_{i}$ bits; and
$-R_{i}$ is the identifier of the symbol composition $\left(N_{i}^{1}, \ldots, N_{i}^{r}\right)$ among all possible tuples of $r$ numbers that add up to $u .{ }^{1} R_{i}$ consists of $\left\lceil\log \binom{u+r-1}{r-1}\right\rceil \leq\lceil r \log (u+1)\rceil$ bits.

Our compressed representation of $S$ consists of storage of the following information:
—a bit sequence $I$ obtained by concatenating all variable-length identifiers $I_{i}$;
—a bit sequence $R$ obtained by concatenating all fixed-length identifiers $R_{i}$;
—a table $E=E_{N^{1}, \ldots, N^{r}}$ for every possible symbol composition ( $N^{1}, \ldots, N^{r}$ ) summing up to $u$. Each entry of $E$ corresponds to a different $u$-length block $G$ (with the proper symbol composition $\left(N^{1}, \ldots, N^{r}\right)$ ) and stores the answers to all $\operatorname{Rank}_{c}(G, q)$ queries, where $1 \leq q \leq u$ and $c \in[1, r]$. Indexes $I_{i}$ are such that $E\left[I_{i}\right]$ stores Rank ${ }_{c}$-information for the block $S_{i}$. Tables $E$ do not depend on $S$, but just on $u$;

[^0]

FIG. 1. A graphical description of the algorithm solving rank queries on sequences. Precisely, we illustrate the case $\operatorname{Rank}_{c}(S, q)$, where $q=i \cdot u+l$. The final " + " is the answer.
-a table $F$ whose entries are indexed by all possible symbol compositions ( $N^{1}, \ldots, N^{r}$ ) summing up to $u$, and points to the corresponding tables $E_{N^{1}, \ldots, N^{r}}$. Indexes $R_{i}$ are such that $F\left[R_{i}\right]$ points to $E_{N_{i}^{1}, \ldots, N_{i}}$. Also table $F$ does not depend on $S$, but just on $u$;
-information to answer partial sum queries on $L_{i}$, that is, to compute $\sum_{j=1}^{i} L_{j}$ in constant time for any block $i$; and
-information to answer partial sum queries on $N_{i}^{c}$, that is, to compute $\sum_{j=1}^{i} N_{j}^{c}$ in constant time for any block $i$ and symbol $c$.
3.1.2. Solving Queries. To answer queries about position $q$, we first compute the block number $i=\lceil q / u\rceil$ to which $q$ belongs and the offset $\ell=q-(i-1) u$ inside this block. Then we compute $E=F\left[R_{i}\right]$, the table of entries corresponding to block $i$, and $G=E\left[I_{i}\right]$, namely the entry of $E$ corresponding to block $i$. Note that since $I_{i}$ values use variable numbers of bits, we need to know which are the starting and ending positions of the representation for $I_{i}$ in the sequence. These are $1+\sum_{j=1}^{i-1} L_{j}$ and $\sum_{j=1}^{i} L_{j}$, respectively, which are known in constant time because we have partial sum information on $L_{i}$.

Now, to answer $\operatorname{Rank}_{c}(S, q)$ we evaluate (in constant time) the partial sum $\sum_{j=1}^{i-1} N_{j}^{c}$ and add $\operatorname{Rank}_{c}(G, \ell)$. To answer $S[q]$ we simply give $G[\ell]$. Both queries take constant time. Figure 1 graphically illustrates the rank computation.
3.1.3. Space Usage. First notice that $u H_{0}\left(S_{i}\right)=\log \left(\begin{array}{c}N_{i}^{1}, \ldots, N_{i}^{\prime}\end{array}\right)$, and thus

$$
\begin{align*}
\sum_{i=1}^{\lceil n / u\rceil} u H_{0}\left(S_{i}\right) & =\sum_{i=1}^{\lceil n / u\rceil} \log \binom{u}{N_{i}^{1}, \ldots, N_{i}^{r}}=\log \prod_{i=1}^{\lceil n / u\rceil}\binom{u}{N_{i}^{1}, \ldots, N_{i}^{r}} \\
& \leq \log \binom{n}{n_{1}, \ldots, n_{r}}=n H_{0}(S), \tag{1}
\end{align*}
$$

where $n_{c}$ is the total number of occurrences of character $c$ in $S$. The inequality holds because distributing $N_{i}^{c}$ symbols over block $S_{i}$ is just one possible way to distribute $n_{c}$ symbols over $S$ [Pagh 1999]. This result permits us to bound the length of the sequence $I$ as

$$
\begin{aligned}
\sum_{i=1}^{\lceil n / u\rceil} L_{i} & =\sum_{i=1}^{\lceil n / u\rceil}\left\lceil\log \binom{u}{N_{i}^{1}, \ldots, N_{i}^{r}}\right\rceil \leq \sum_{i=1}^{\lceil n / u\rceil} u H_{0}\left(S_{i}\right)+\lceil n / u\rceil \\
& \leq n H_{0}(S)+O\left(n / \log _{r} n\right)
\end{aligned}
$$

Let us now consider the sequence $R$. The number of different tuples ( $N^{1}, \ldots, N^{r}$ ) that add up $u$ is $\binom{u+r-1}{r-1} \leq(u+1)^{r}$. Hence, it is enough to use $\lceil r \log (u+1)\rceil$ bits for each $R_{i}$ (which actually is enough to describe any tuple of $r$ numbers in $[0, u]$ ). Accumulated over the $\lceil n / u\rceil$ blocks, this requires $O\left(r n \log \log n / \log _{r} n\right)$ bits.

We consider now the structures to answer partial sum queries [Pagh 1999], namely $\sum_{j=1}^{i} N_{j}^{c}$ and $\sum_{j=1}^{i} L_{j}$. Both structures are similar. Let us first concentrate on the $L_{j}$ 's, whose upper bounds are $L_{i} \leq\lceil u \log r\rceil$ since $\left(\begin{array}{c}N_{i}^{1}, \ldots, N_{i}^{\prime}\end{array}\right) \leq r^{u}$. Recall that we need to answer partial sum queries over the sequence of integers $L=L_{1}, L_{2}, \ldots, L_{t}$, where $t=\lceil n / u\rceil$. Since $L_{i} \leq\lceil u \log r\rceil$, each partial sum over $L$ does not exceed $n\lceil\log r\rceil$ and can be represented in $\lceil\log (n\lceil\log r\rceil)\rceil$ bits. Divide $L$ into blocks of this length, $\lceil\log (n\lceil\log r\rceil)\rceil$, and store the full partial sums for the beginning of each block. This requires exactly $t=O\left(n / \log _{r} n\right)$ bits. Inside each block, store the partial sums relative to the block beginning. These latter partial sums cannot exceed $\lceil u \log r\rceil\lceil\log (n\lceil\log r\rceil)\rceil$ because of the upper bound on the $L_{i}$ 's and the length of $L$-blocks. Hence we need $O(\log u+\log \log r+\log \log n)=$ $O(\log \log n)$ bits for each partial sum within each block of $L$. Thus we need $O(|L| \log \log n)=O(t \log \log n)=O\left(n \log \log n / \log _{r} n\right)$ bits overall for the partial sum information on $L$. A partial sum query on $L_{i}$ is answered in constant time by adding the partial sum of the block of $L$ that contains $L_{i}$ and the relative partial sum of $L_{i}$ inside that block. The same technique can be applied to sequences $N^{c}$, whose values are in the range $[0, u]$, to obtain $O\left(r n \log \log n / \log _{r} n\right)$ bits of space because there are $r$ sequences to index.

Finally, let us consider tables $E$ and $F$. The total number of entries over all $E_{N^{1}, \ldots, N^{r}}$ tables is clearly $r^{u}$, since each sequence of $u$ symbols over [1, $r$ ] belongs to exactly one symbol composition. For each such entry $G$, we explicitly store the sequence itself plus the answers to all $\operatorname{Rank}_{c}(G, q)$ queries, $c \in[1, r], 1 \leq q \leq u$. This storage requires $O(u \log r+r u \log u)$ bits. Added over all entries of all $E$ tables, we have $O\left(r^{u}(u \log r+r u \log u)\right)=O\left(\sqrt{n} r \log _{r} n \log \log n\right)$ bits, which is $o\left(r n \log \log n / \log _{r} n\right)$. Table $F$ has necessarily fewer entries than $E$, since there is at least one distinct entry of $E$ for each $\left(N^{1}, \ldots, N^{r}\right)$ symbol composition in $F$. Each entry in $F$ points to the corresponding table $E_{N^{1}, \ldots, N^{r}}$. If we concatenate all $E_{N^{1}, \ldots, N^{r}}$ tables into a supertable of $r^{u}$ entries, then $F$ points inside this supertable to the first entry of the corresponding table, and this requires $O(u \log r)$ bits per entry. Overall this adds $O\left(r^{u} u \log r\right)$ bits, which is negligible compared to the size of $E$.

We remark that the simpler solution of storing indexes $P_{i}=F\left[R_{i}\right]+I_{i}$ directly pointing to the large supertable $E$ would require $n \log r$ bits, as the pointers are as long as the sequences represented. This would defeat the whole scheme. Thus we
use table $F$ as an intermediary so as to store the smaller $R_{i}$ (subtable identifier) and $I_{i}$ (index relative to the subtable).
3.1.4. Solving $^{\operatorname{Select}}(S, q)$ Queries. The solution to $\operatorname{Select}_{c}(S, q)$ queries on binary sequences proposed in Raman et al. [2002, Lem. 2.3] divides the sequence into blocks of size $u$ (with the same formula we use for $u$, with $r=2$ ) and makes use of a sequence $A$, so that $A_{i}$ is the number of bits set in the $i$ th block. In our scheme, sequence $A$ corresponds to sequence $N^{c}$ for each character $c \in[1, r]$. We can use exactly the same scheme of Raman et al. [2002] for each of our sequences $N^{c}$. They need precisely the same partial sum queries we already considered for $N^{c}$, as well as other structures that require $O(n \log (u) / u)$ bits per sequence $N^{c}$. They also need to have all $\operatorname{Select}_{c}(G, q)$ queries precomputed for each possible block $G$, which we can add to our $E$ tables for additional $O\left(r^{u} r u \log u\right)$ bits. Overall, the solution needs $O(r n \log (u) / u)=O\left(r n \log \log n / \log _{r} n\right)$ additional bits of space.
Theorem 3.1. Let $S[1, n]$ be a sequence of numbers in $[1, r]$, with $2 \leq r \leq$ $\sqrt{n}$. There exists a data structure, using $n H_{0}(S)+O\left(r(n \log \log n) / \log _{r} n\right)$ bits of space, that supports queries $\operatorname{Rank}_{c}(S, q)$ and $\operatorname{Select}_{c}(S, q)$ and retrieves $S[q]$, all in constant time.

The theorem is a generalization of the results in Pagh [1999] and Raman et al. [2002], which use $n H_{0}(S)+O((n \log \log n) / \log n)$ bits of space to represent a binary sequence $S(r=2)$ so as to answer $\operatorname{Rank}_{c}(S, q)$ and $\operatorname{Select}_{c}(S, q)$ queries in constant time. Note that for binary sequences, queries $S[q]$ can be easily answered in constant time by finding $c \in\{0,1\}$ such that $\operatorname{Rank}_{c}(S, q)-\operatorname{Rank}_{c}(S, q-1)=1$, whereas we had to provide direct access to $G[\ell]$. Moreover, with binary sequences one can use $R_{i}=i$, while we needed explicit pointers to an intermediate table $F$.
As we have already observed, the preceding result is interesting only for alphabets of size $r=o(\log n / \log \log n)$, since otherwise the space occupancy of the data structure is $\Omega(n \log r)$. In the next section we show how to extend this result to alphabets of polylogarithmic size.
3.2. Generalized Wavelet Trees. In this section we use the representation of sequences developed in the previous section to build an improved sequence representation which better adapts to the range of different symbols represented. Albeit we solve exactly the same problem, we will change notation a bit for clarity. This time our sequence $S[1, n]$ will be a sequence of symbols over an alphabet $\Sigma=[1,|\Sigma|]$, so that $r \leq|\Sigma|$ will be reserved to applications of Theorem 3.1. Actually, for $r=|\Sigma|$ the data structure we are going to introduce will be essentially the data structure of Theorem 3.1.
Let us recall the basic ideas underlying the (binary) wavelet tree [Grossi et al. 2003]. Consider a balanced binary tree $\mathcal{T}$ whose leaves contain the characters of the alphabet $\Sigma$. Moreover, $\mathcal{T}$ has height $O(\log |\Sigma|)$. Each node $u$ of $\mathcal{T}$ is associated with a string $S_{u}$ that represents the subsequence of $S$ containing only the characters that are stored into leaves descending from $u$. The root is thus associated with the entire $S$. The node $u$ of the wavelet tree does indeed store a binary image of the sequence $S_{u}$, denoted by $B_{u}$, such that $B_{u}[i]=1$ if the character $S_{u}[i]$ descends by the right child of $u$, and $B_{u}[i]=0$ otherwise. By representing every binary sequence $B_{u}$ with the data structure of Raman et al. [2002], we get a data structure supporting $\operatorname{Rank}_{c}(S, q)$, $\operatorname{Select}_{c}(S, q)$, and $S[q]$ queries in $O(\log |\Sigma|)$ time using $n H_{0}(S)+o(n \log |\Sigma|)$ bits of space.
3.2.1. The $r$-ary Wavelet Tree. Let us consider an $r$-ary balanced tree whose leaves are associated with symbols of the alphabet $\Sigma$. This $r$-ary tree has height at most $1+\log _{r}|\Sigma|$. As in a (binary) wavelet tree, each node $v$ is associated with a subsequence $S_{v}$ of $S[1, n]$ formed just by the symbols descending from $v$. Unlike a (binary) wavelet tree, the subsequence $S_{v}$ is stored in $v$ as a sequence of integers in the range $[1, r]$. Precisely, let $v$ be a node with children $v_{1} \ldots v_{r}$, and let $\Sigma_{v}$ be the set of symbols descending from $v$. Because of the balance of the tree, $\Sigma_{v}$ is actually split into $r$ equally-sized subsets $\Sigma_{v_{1}} \ldots \Sigma_{v_{r}}$, which are integral ranges of size $\left|\Sigma_{v_{i}}\right| \approx\left|\Sigma_{v}\right| / r$. Therefore, the sequence $S_{v}$ is represented as a sequence of $n_{v}=\left|S_{v}\right|$ integers in the range $[1, r]$ such that $S_{v}[q]=j$ whenever $S_{v}[q] \in \Sigma_{v_{j}}$. The data structure of Theorem 3.1 is finally built over $S_{v}$ and stored at node $v$ so as to answer queries $S_{v}[q], \operatorname{Rank}_{j}\left(S_{v}, q\right)$, and $\operatorname{Select}_{j}\left(S_{v}, q\right)$ in constant time.

A technical detail is that we concatenate all the sequences $S_{v}$ lying at the tree level $h$, and store them into one unique long sequence $S^{h}$. All these level-wise sequences have the same length of $S$, namely $n$. As we go down/up the tree, it is easy to maintain in constant time the index $q^{*}+1$ where the current node sequence $S_{v}$ starts inside the level sequence $S^{h}$. To achieve this, each node $v$ maintains also a vector $C_{v}[1, r]$ such that $C_{v}[j]$ is the number of occurrences in $S_{v}$ of symbols in $[1, j-1]$. Now assume that we are at node $v$ and its sequence $S_{v}$ starts at index $q^{*}+1$ of $S^{h}$; then the sequence $S_{v_{j}}$ of the $j$ th child of $v$ starts at $q^{*}+C_{v}[j]+1$ in $S^{h+1}$. Conversely, assume that we are at node $v_{j}$ and its sequence $S_{v_{j}}$ starts at index $q^{*}+1$ of $S^{h+1}$; then the sequence $S_{v}$ of the parent $v$ of $v_{j}$ starts at $q^{*}-C_{v}[j]+1$ in $S^{h}$. Notice that we need to store pointers (with negligible extra space) to find the $C$ vectors of children or parents, or we can take advantage of the tree being almost perfect to avoid such pointers. We also need, for the bottom-up traversal required to implement select (see next), $|\Sigma|$ pointers to the leaves of the $r$-ary wavelet tree.
—Solving queries: To compute $\operatorname{Rank}_{c}(S, q)$, we start at the root node $v$ and determine in constant time the subset $\Sigma_{v_{j}}$ to which $c$ belongs by a simple algebraic calculation. We then compute the position corresponding to $q$ in $S_{v_{j}}$, namely $q_{v_{j}}=$ $\operatorname{Rank}_{j}\left(S_{v}, q\right)$. We then recursively continue with $q=q_{v_{j}}$ at node $v_{j}$. We eventually reach a tree leaf $v_{l}$ (corresponding to the subset $\{c\} \subseteq \Sigma$ ) for which we have the answer to our original query $\operatorname{Rank}_{c}(S, q)=q_{v_{l}}$. On the other hand, to determine $S[q]$, we start at the root node $v$ and obtain $j=S_{v}[q]$, so that $S[q] \in \Sigma_{v_{j}}$. Then we continue recursively with node $v_{j}$ and $q=q_{v_{j}}=\operatorname{Rank}_{j}\left(S_{v}, q\right)$ as before, until we reach a leaf $v_{l}$ where $\Sigma_{v_{l}}=\{S[q]\}$ is finally determined. Both queries take $O\left(\log _{r}|\Sigma|\right)$ time.

To compute $\operatorname{Select}_{c}(S, q)$, instead, we proceed bottom-up. We identify the leaf $v_{l}$ corresponding to subset $\{c\}$ and then proceed upwards. At leaf $v_{l}$ (not actually represented in the tree), we initialize $q_{v_{l}}=q$. This is the position we want to track upwards in the tree. Now, letting $v$ be the parent of $v_{j}$, then $q_{v}=\operatorname{Select}_{j}\left(S_{v}, q_{v_{j}}\right)$ is the position of $S_{v_{j}}\left[q_{v_{j}}\right]$ in $S_{v}$. We eventually reach the root, with $q_{\text {root }}=\operatorname{Select}_{c}(S, q)$, in $O\left(\log _{r}|\Sigma|\right)$ time.

It goes without saying that since we do not represent sequences $S_{v}$ but levelwise sequences $S^{h}$, in the preceding calculations we need to take care of the latter. Assume that our current sequence $S_{v}$ starts at position $q^{*}+1$ in $S^{h}$. Then, queries over $S_{v}$ are translated to queries over $S^{h}$ as follows: $S_{v}[q]=$ $S^{h}\left[q^{*}+q\right], \operatorname{Rank}_{j}\left(S_{v}, q\right)=\operatorname{Rank}_{j}\left(S^{h}, q^{*}+q\right)-\operatorname{Rank}_{j}\left(S^{h}, q^{*}\right), \operatorname{and}_{\operatorname{Select}}^{j}\left(S_{v}, q\right)=$ $\operatorname{Select}_{j}\left(S^{h}, \operatorname{Rank}_{j}\left(S^{h}, q^{*}\right)+q\right)$.
-Space usage: An immediate advantage of having all sequences $S^{h}[1, n]$ over the same alphabet $[1, r]$ is that all tables $E$ and $F$ are the same for all levels, thus taking $o\left((r n \log \log n) / \log _{r} n\right)$ bits overall. All the other $O\left((r n \log \log n) / \log _{r} n\right)$ size structures used to prove Theorem 3.1 total $O(\log |\Sigma|(r n \log \log n) / \log n)$ bits of space by adding up all the $O\left(\log _{r}|\Sigma|\right)$ levels. The structures $C_{v}$ need $O(r \log n)$ bits each, and there is one $C_{v}$ array per nonleaf node $v$. This totals $O\left(\frac{|\Sigma|}{r-1} r \log n\right)=$ $O(|\Sigma| \log n)$ bits. This space includes also the pointers to leaves and the parent-child pointers in the tree, if used.

Let us consider now the entropy-related part. For each nonleaf node $v$ at treelevel $h$, with children $v_{1}, \ldots, v_{r}$, sequence $S_{v}$ spans at most $2+\left\lfloor n_{v} / u\right\rfloor$ blocks in $S^{h}$ (recall from Section 3.1 that the sequence is divided into blocks of length $u=\left\lfloor\frac{1}{2} \log n\right\rfloor$ and that $\left.n_{v}=\left|S_{v}\right|\right)$. The sum of local zero-order entropies $u H_{0}\left(S_{i}^{h}\right)$ for the $\left\lfloor n_{v} / u\right\rfloor$ blocks is a lower bound to $n_{v} H_{0}\left(S_{v}\right)$ (recall Eq. (1)). As for the other two blocks, we simply assume that they take the maximum $u\lceil\log r\rceil=O(\log n)$ bits. We have at most $\frac{r}{r-1}|\Sigma|$ boundaries over the whole tree. Hence summing over all the sequence boundaries, the space overhead induced by all partial blocks is $O(|\Sigma| \log n)$ bits.

Thus, let us focus on the term $n_{v} H_{0}\left(S_{v}\right)$. Note that this is

$$
\begin{aligned}
-n_{v} \sum_{j=1}^{r} \frac{n_{v_{j}}}{n_{v}} \log \frac{n_{v_{j}}}{n_{v}} & =-\sum_{j=1}^{r} n_{v_{j}} \log n_{v_{j}}+\sum_{j=1}^{r} n_{v_{j}} \log n_{v} \\
& =n_{v} \log n_{v}-\sum_{j=1}^{r} n_{v_{j}} \log n_{v_{j}}
\end{aligned}
$$

If we add this term over all the nodes $v$ in the tree, we get a sort of telescopic sum in which the second terms $-n_{v_{j}} \log n_{v_{j}}$ computed for $v$ will cancel the first (positive) term of the formula derived for children $v_{j}$ 's. Therefore, after all cancellations, the only surviving terms are the term $n \log n$ corresponding to the tree root, and the terms $-n_{u_{l}} \log n_{u_{l}}$ corresponding to the parents of the tree leaves (where $n_{u_{l}}=n_{c}$ for some $c \in \Sigma$, where $n_{c}$ is the frequency of character $c$ ). This is

$$
n \log n-\sum_{c \in \Sigma} n_{c} \log \left(n_{c}\right)=n H_{0}(S)
$$

THEOREM 3.2. Let $S[1, n]$ be a string over an arbitrary alphabet $\Sigma$. The $r$-ary wavelet tree built on $S$, for $2 \leq r \leq \min (|\Sigma|, \sqrt{n})$, uses $n H_{0}(S)+O(|\Sigma| \log n)+$ $O(\log |\Sigma|(r n \log \log n) / \log n)$ bits of storage and supports in $O\left(\log _{r}|\Sigma|\right)$ time the queries $S[q]$, $\operatorname{Rank}_{c}(S, q)$, and $\operatorname{Select}_{c}(S, q)$ for any $c \in \Sigma$ and $1 \leq q \leq n$.

Moreover, if $|\Sigma|=O(\operatorname{poly} \log (n))$, thenr can be chosen so that the resulting $r$-ary wavelet tree supports all queries in constant time and takes $n H_{0}(S)+O\left(n / \log ^{\varepsilon} n\right)$ bits of space for any constant $0<\varepsilon<1$.

Proof. The first part of the theorem, for a general $r$, is a consequence of the development in this section. For the last sentence, note that by choosing $r=|\Sigma|^{1 / \kappa}$, for constant $\kappa>0$, we can support the query operations in constant time $O(\kappa)$. Now, if $|\Sigma|=O(\operatorname{poly} \log (n))=O\left((\log n)^{d}\right)$, then we can choose any $\kappa>d$ to obtain $O\left(d n(\log \log n)^{2} /(\log n)^{1-d / \kappa}\right)$ space overhead. For any constant $0<$ $\varepsilon<1$, we choose $\kappa \geq d /(1-\varepsilon)$ to ensure that $O\left(n(\log \log n)^{2} /(\log n)^{1-d / \kappa}\right)=$ $O\left(n / \log ^{\varepsilon} n\right)$.

The theorem is a generalization upon the (binary) wavelet tree data structure [Grossi et al. 2003], taking $n H_{0}(S)+O(\log |\Sigma|(n \log \log n) / \log n)$ space and answering the same queries in $O(\log |\Sigma|)$ time. The last part shows that when $|\Sigma|=O(\operatorname{polylog}(n))$, the generalization obtains essentially the same space (up to lower-order terms) and reduces query times to a constant. The case of larger alphabets deserves a separate corollary.

COROLLARY 3.3. Let $S[1, n]$ be a string over an alphabet $\Sigma$. If we choose $r=O\left(\log n /(\log \log n)^{2}\right)$, the $r$-ary wavelet tree built on $S$ uses $n H_{0}(S)+$ $O(|\Sigma| \log n)+o(n \log |\Sigma|)$ bits and supports in $O(\log |\Sigma| / \log \log n)$ time the queries $S[q]$, $\operatorname{Rank}_{c}(S, q)$, and $\operatorname{Select}_{c}(S, q)$ for any $c \in \Sigma$ and $1 \leq q \leq n$. Note that if $|\Sigma|=o(n)$, the space occupancy simplifies to $n H_{0}(S)+o(n \log |\Sigma|)$.

## 4. Compressed Representation of Full-Text Indexes

We will now apply the results of the previous section to build a new implementation of the FM-index concept. We need first to explain the FM-index concept in full detail, that is, the Burrows-Wheeler transform and the backward search mechanism, highlighting the time dependence on alphabet size $|\Sigma|$. Also, the compression boosting technique [Ferragina et al. 2005] will be central to our solution. We introduce these earlier developments in Sections 4.1 to 4.4 and then introduce our new result in Section 4.5.

Hereafter we assume that $T[1, n]$ is the text we wish to index, compress, and query. $T$ is drawn from an alphabet $\Sigma$ of size $|\Sigma|$. By $T[i]$ we denote the $i$ th character of $T$, while $T[i, n]$ denotes the $i$ th text suffix and $T[1, i]$ denotes the $i$ th text prefix. A substring of $T$ is any $T[i, j]$. We write $|w|$ to denote the length of string $w$.

Our final goal is to answer substring queries using a compressed representation of $T$. In other words, we wish to find out whether a given pattern $P[1, p]$ occurs as a substring of $T$ (existence query), how many times it occurs (counting query), and at which positions (locating query). Also, as $T$ is compressed, we need to support the retrieval of any substring of $T$ (context query). If the compressed representation of $T$ supports all these queries, we say that the representation is a compressed full-text self-index.
4.1. The $k$ Th-Order Empirical Entropy. Following a well-established practice in information theory, we lower bound the space needed to store a string $T$ by using the notion of empirical entropy. Empirical entropy is similar to the entropy defined in the probabilistic setting with the difference that it is defined in terms of the character frequencies observed in $T$, rather than in terms of character probabilities. The key property of empirical entropy is that it is defined pointwise for any string $T$ and can be used to measure the performance of compression algorithms as a function of the string structure, thus without any assumption on the input source. In a sense, compression bounds produced in terms of empirical entropy are worst-case measures.

Just as defined for sequences, the zero-order empirical entropy of $T$ is defined as $H_{0}(T)=-\sum_{c}\left(n_{c} / n\right) \log \left(n_{c} / n\right)$, where $n_{c}$ is the number of occurrences of alphabet character $c$ in $T$, and $n=\sum_{c} n_{c}=|T|$. To introduce the concept of $k t h$-order empirical entropy we need to define what is a context. A length- $k$ context $w$ in $T$ is one of its substrings of length $k$. Given $w$, we denote by $w_{T}$ the string

|  | $T^{b w t}$ |  |
| :--- | :--- | :--- |
| mississippi\# |  | \# mississipp i |
| ississippi\#m |  | i \#mississip p |
| ssissippi\#mi | i ppi\#missis s |  |
| sissippi\#mis | i ssippi\#mis s |  |
| issippi\#miss | i ssissippi\# m |  |
| ssippi\#missi | m ississippi \# |  |
| sippi\#missis | p i\#mississi p |  |
| ippi\#mississ | p pi\#mississ i |  |
| ppi\#mississi | s ippi\#missi s |  |
| pi\#mississip | s issippi\#mi s |  |
| i\#mississipp |  | s sippi\#miss i |
| \#mississippi |  |  |

Fig. 2. Example of Burrows-Wheeler transform for the string $T=$ mississippi. The matrix on the right has rows sorted in lexicographic order. The output of the BWT is the last column; in this example, the string ipssm\#pissii.
formed by concatenating all the symbols following the occurrences of $w$ in $T$, taken from left-to-right. For example, if $T=$ mississippi, then $\mathrm{s}_{T}=\operatorname{sisi}$ and $\mathrm{si}_{T}=$ sp. The $k$ th-order empirical entropy of $T$ is defined as

$$
\begin{equation*}
H_{k}(T)=\frac{1}{n} \sum_{w \in \Sigma^{k}}\left|w_{T}\right| H_{0}\left(w_{T}\right) \tag{2}
\end{equation*}
$$

The $k$ th-order empirical entropy $H_{k}(T)$ is a lower bound to the output size of any compressor which encodes each character of $T$ using a uniquely decipherable code that depends only on the character itself and on the $k$ characters preceding it. For any $k \geq 0$, we have $H_{k}(T) \leq \log |\Sigma|$. Note that for strings with many regularities we may have $H_{k}(T)=o(1)$. This is unlike the entropy defined in the probabilistic setting, which is always a constant. As an example, for the family of texts $T=(a b)^{n / 2}$ we have $H_{0}(T)=1$ and $H_{k}(T)=O((\log n) / n)$ for any $k \geq 1$. $H_{k}$ can be similarly defined with the symbols preceding (instead of following) the contexts, and the result is the same up to lower order terms [Ferragina and Manzini 2005]. We will use the definitions interchangeably in the following.
4.2. The Burrows-Wheeler Transform. Burrows and Wheeler [1994] introduced a new compression algorithm based on a reversible transformation that is now called the Burrows-Wheeler transform (BWT). The BWT consists of three basic steps (see Figure 2): (1) Append at the end of $T$ a special character \# smaller than any other text character; (2) form a conceptual matrix $\mathcal{M}_{T}$ whose rows are the cyclic shifts of the string $T$ \# sorted in lexicographic order; and (3) construct the transformed text $T^{b w t}$ by taking the last column of matrix $\mathcal{M}_{T}$. Notice that every column of $\mathcal{M}_{T}$, hence also the transformed text $T^{b w t}$, is a permutation of $T \#$. In particular, the first column of $\mathcal{M}_{T}$, call it $F$, is obtained by lexicographically sorting the characters of $T$ \# (or equally, the characters of $T^{b w t}$ ).

We remark that the BWT itself is not a compression algorithm, since $T^{b w t}$ is just a permutation of $T \#$. However, if $T$ has "small" entropy the transformed string $T^{b w t}$ contains long runs of identical characters and turns out to be highly compressible [Burrows and Wheeler 1994; Manzini 2001].

Because of the special character \#, when we sort the rows of $\mathcal{M}_{T}$ we are essentially sorting the suffixes of $T$. Therefore, there is a strong relation between

```
Algorithm count \((P[1, p])\)
    \(i \leftarrow p, c \leftarrow P[p]\), First \(\leftarrow 1\), Last \(\leftarrow n\);
    while \(((\) First \(\leq\) Last \()\) and \((i \geq 1))\) do
        \(c \leftarrow P[i] ;\)
        First \(\leftarrow C[c]+\operatorname{Occ}(c\), First -1\()+1\);
        Last \(\leftarrow C[c]+\operatorname{Occ}(c\), Last \()\);
        \(i \leftarrow i-1 ;\)
    if (Last < First) then return "no rows prefixed by \(P[1, p]\) " else return (First, Last).
```

FIG. 3. Algorithm count for finding the set of rows prefixed by $P[1, p]$, and thus for counting the pattern occurrences $o c c=$ Last - First +1 . Recall that $C[c]$ is the number of text characters which are alphabetically smaller than $c$, and that $\operatorname{Occ}(c, q)$ denotes the number of occurrences of character $c$ in $T^{b w t}[1, q]$.
the matrix $\mathcal{M}_{T}$ and the suffix array built on $T$. The matrix $\mathcal{M}_{T}$ has also other remarkable properties; to illustrate them we introduce the following notation:
-Let $C[$ ] denote the array of length $|\Sigma|$ such that $C[c]$ contains the total number of text characters which are alphabetically smaller than $c$.
-Let $\operatorname{Occ}(c, q)$ denote the number of occurrences of character $c$ in the prefix $T^{b w t}[1, q]$. In our sequence terminology, $\operatorname{Occ}(c, q)=\operatorname{Rank}_{c}\left(T^{b w t}, q\right)$.

- Let $L F(i)=C\left[T^{b w t}[i]\right]+\operatorname{Occ}\left(T^{b w t}[i], i\right)$.
$L F()$ stands for last-to-first column mapping, since the character $T^{b w t}[i]$, in the last column of $\mathcal{M}_{T}$, is located in the first column $F$ at position $L F(i)$. For example, in Figure 2 we have $L F(10)=C[\mathrm{~s}]+\operatorname{Occ}(\mathrm{s}, 10)=12$; and in fact $T^{b w t}[10]$ and $F[L F(10)]=F[12]$ both correspond to the first s in the string mississippi.

The $L F($ ) mapping allows us to scan the text $T$ backward. Specifically, if $T[k]=T^{b w t}[i]$ then $T[k-1]=T^{b w t}[L F(i)]$. For example, in Figure 2 we have that $T[3]=\mathrm{s}$ is the tenth character of $T^{b w t}$ and we correctly have $T[2]=$ $T^{b w t}[L F(10)]=T^{b w t}[12]=$ i [Ferragina and Manzini 2005].
4.3. The FM-Index. The FM-index is a self-index that allows one to efficiently search for the occurrences of an arbitrary pattern $P[1, p]$ as a substring of the text $T[1, n]$. Pattern $P$ is provided online, whereas the text $T$ is given to be preprocessed in advance. The number of pattern occurrences in $T$ is hereafter indicated by occ.

The FM-index consists, in essence, of the data structures required to compute $C[]$, $\operatorname{Occ}()$, and $L F()$. The first is directly stored in $|\Sigma| \log n$ bits. To compute $\operatorname{Occ}(c, q)$ in constant time, the FM-index stores a compressed representation of $T^{b w t}$ together with some auxiliary information. This also gives the tools to compute $L F(i)$, provided we have access to $T^{b w t}[i]$. This is obtained in $O(|\Sigma|)$ time by linearly searching for the only $c \in \Sigma$ such that $\operatorname{Occ}(c, q) \neq \operatorname{Occ}(c, q-1)$. The two key procedures to operate on the FM-index are: the counting of the number of pattern occurrences (shortly, count), and the location of their positions in the text $T$ (shortly, locate). Note that the counting process returns the value occ, whereas the location process returns occ distinct integers in the range $[1, n]$.
Figure 3 sketches the pseudocode of the counting operation that works "backwards" in $p$ phases, hence numbered from $p$ to 1 . The $i$ th phase preserves the following invariant: The parameter First points to the first row of the BWT matrix $\mathcal{M}_{T}$ prefixed by $P[i, p]$, and the parameter Last points to the last row of $\mathcal{M}_{T}$ prefixed by $P[i, p]$. After the final phase, $P$ prefixes the rows between First and

```
Algorithm locate \((i)\)
    \(i^{\prime} \leftarrow i, t \leftarrow 0 ;\)
    while row \(i^{\prime}\) is not marked do
        \(i^{\prime} \leftarrow L F\left[i^{\prime}\right] ;\)
        \(t \leftarrow t+1 ;\)
    return \(\operatorname{Pos}\left(i^{\prime}\right)+t\)
```

Fig. 4. Algorithm locate for the computation of $\operatorname{Pos}(i)$.
Last and thus, according to the properties of matrix $\mathcal{M}_{T}$ (see Section 4.2), we have $o c c=$ Last - First +1 . It is easy to see that the running time of count is dominated by the cost of the $2 p$ computations of the values $\operatorname{Occ}()$.

Given the range (First, Last), we now consider the problem of locating the positions in $T$ of these pattern occurrences. We notice that every row in $\mathcal{M}_{T}$ is prefixed by some suffix of $T$. For example, in Figure 2, the fourth row of $\mathcal{M}_{T}$ is prefixed by the text suffix $T[5,11]=$ issippi. Then, for $i=$ First, First $+1, \ldots$, Last we use procedure locate( $(i)$ to find the starting position in $T$ of the suffix that prefixes the $i$ th row $\mathcal{M}_{T}[i]$. Such a position is denoted hereafter by $\operatorname{Pos}(i)$, and the pseudocode of locate is given in Figure 4. The intuition underlying its functioning is simple. We scan backwards the text $T$ using the $L F$ () mapping (see Section 4.2) until a marked position is met. If we mark one text position every $\Theta\left(\log ^{1+\varepsilon} n\right)$, for some constant $\varepsilon>0$, the while loop is executed $O\left(\log ^{1+\varepsilon} n\right)$ times. Since the computation of $L F(i)$ is done via at most $|\Sigma|$ computations of Occ( ), we have that locate takes $O\left(|\Sigma| \log ^{1+\varepsilon} n\right)$ time. The space required by the marked positions is $\Theta\left(n / \log ^{\varepsilon} n\right)$ bits. Combining the observations on locate with the ones for count, we get [Ferragina and Manzini 2005] the following theorem.

THEOREM 4.1. For any string $T[1, n]$ drawn from a constant-sized alphabet $\Sigma$, the FM-index counts the occurrences of any pattern $P[1, p]$ within $T$, taking $O(p)$ time. The location of each pattern occurrence takes $O\left(|\Sigma| \log ^{1+\varepsilon} n\right)$ time for any constant $\varepsilon>0$. The size of the FM-index is bounded by $5 n H_{k}(T)+o(n)$ bits, for any fixed $k$.

In order to retrieve the content of $T\left[l_{1}, l_{2}\right]$, we must first find the row in $\mathcal{M}_{T}$ that corresponds to $l_{2}$, and then issue $\ell=l_{2}-l_{1}+1$ backward steps in $T$, using the $L F$ ( ) mapping. Starting at the lowest marked text position that follows $l_{2}$, we perform $O\left(\log ^{1+\varepsilon} n\right)$ steps until reaching $l_{2}$. Then, we perform $\ell$ additional LF-steps to collect the text characters. The resulting complexity is $O\left(\left(\ell+\log ^{1+\varepsilon} n\right)|\Sigma|\right)$.

As we mentioned in the Introduction, the main drawback of the FM-index is that, hidden in the $o(n)$ term of the space bound, there are constants which depend exponentially on the alphabet size $|\Sigma|$. In Section 4.5 we describe our new implementation of the FM-index concept, which takes $n H_{k}(T)+o(n)$ bits and allows the computation of $\operatorname{Occ}(c, q)$ and $T^{b w t}[i]$ in $O(1)$ time for a reasonable range of alphabet sizes, namely, $|\Sigma|=O(\operatorname{polylog}(n))$.
4.4. COMPRESSION BOOSTING. The concept of compression boosting has been recently introduced in Ferragina et al. [2005], opening the door to a new approach to data compression. The key idea is that one can take an algorithm whose performance can be bounded in terms of the zero-order entropy and obtain, via the booster, a new compressor whose performance can be bounded in terms of the $k$ th-order
entropy, simultaneously for all $k$. Putting it another way, one can take a compression algorithm that uses no context information at all and, via the boosting process, obtain an algorithm that automatically uses the "best possible" contexts.

For technical reasons we need a boosting theorem which is slightly different from the one in Ferragina et al. [2005]. However, the proof of Theorem 4.2 is obtained by a straightforward modification of the proof of Lemma 4.6 in Ferragina et al. [2005].

THEOREM 4.2. Let $\mathcal{A}$ be an algorithm which compresses any string $S$ in less than $|S| H_{0}(S)+f(|S|)$ bits, where $f()$ is a nondecreasing concave function. Given $T[1, n]$, there is an $O(n)$-time procedure that computes a partition $S_{1}, S_{2}, \ldots, S_{z}$ of $T^{b w t}$ such that for any $k \geq 0$, we have

$$
\sum_{i=1}^{z}\left|\mathcal{A}\left(S_{i}\right)\right| \leq \sum_{i=1}^{z}\left(\left|S_{i}\right| H_{0}\left(S_{i}\right)+f\left(\left|S_{i}\right|\right)\right) \leq n H_{k}(T)+|\Sigma|^{k} f\left(n /|\Sigma|^{k}\right)
$$

Proof. For any $k \geq 0$, let $\hat{S}_{1}, \hat{S}_{2}, \ldots, \hat{S}_{m}$ denote the partition of $T^{b w t}$ such that

$$
\begin{equation*}
\sum_{i=1}^{m}\left|\hat{S}_{i}\right| H_{0}\left(\hat{S}_{i}\right)=n H_{k}(T) \tag{3}
\end{equation*}
$$

Each $\hat{S}_{i}$ is a permutation of one of the strings $w_{T}$ defined in Section 4.1 with $w \in \Sigma^{k}$ [Ferragina et al. 2005, Sect. 3]. Repeating verbatim the proof of Lemma 4.6 in Ferragina et al. [2005] we get that the partition $S_{1}, \ldots, S_{z}$ of $T^{b w t}$ produced by the boosting algorithm is such that

$$
\begin{equation*}
\sum_{i=1}^{z}\left(\left|S_{i}\right| H_{0}\left(S_{i}\right)+f\left(\left|S_{i}\right|\right)\right) \leq \sum_{i=1}^{m}\left(\left|\hat{S}_{i}\right| H_{0}\left(\hat{S}_{i}\right)+f\left(\left|\hat{S}_{i}\right|\right)\right) \tag{4}
\end{equation*}
$$

Since by hypothesis $\left|\mathcal{A}\left(S_{i}\right)\right| \leq\left|S_{i}\right| H_{0}\left(S_{i}\right)+f\left(\left|S_{i}\right|\right)$, from Eqs. (4) and (3) we get

$$
\begin{aligned}
\sum_{i=1}^{z}\left(\left|S_{i}\right| H_{0}\left(S_{i}\right)+f\left(\left|S_{i}\right|\right)\right) & \leq \sum_{i=1}^{m}\left|\hat{S}_{i}\right| H_{0}\left(\hat{S}_{i}\right)+\sum_{i=1}^{m} f\left(\left|\hat{S}_{i}\right|\right) \\
& =n H_{k}(T)+\sum_{i=1}^{m} f\left(\left|\hat{S}_{i}\right|\right) \\
& \leq n H_{k}(T)+|\Sigma|^{k} f\left(n /|\Sigma|^{k}\right),
\end{aligned}
$$

where the last inequality follows from the concavity of $f()$ and the fact that $m \leq|\Sigma|^{k}$.

To understand the relevance of this result, suppose that we want to compress $T[1, n]$ and that we wish to exploit the zero-order compressor $\mathcal{A}$. Using the boosting technique we can first compute the partition $S_{1}, S_{2}, \ldots, S_{z}$ of $T^{b w t}$, and then compress each $S_{i}$ using $\mathcal{A}$. By the previous theorem, the overall space occupancy would be bounded by $\sum_{i}\left|\mathcal{A}\left(S_{i}\right)\right| \leq n H_{k}(T)+|\Sigma|^{k} f\left(n /|\Sigma|^{k}\right)$. Note that the process is reversible because the decompression of each $S_{i}$ retrieves $T^{b w t}$, and from $T^{b w t}$ we can retrieve $T$ using the inverse BWT. Summing up, the booster allows us to compress $T$ up to its $k$ th-order entropy using only the zero-order compressor $\mathcal{A}$. Note that the parameter $k$ is neither known to $\mathcal{A}$ nor to the booster, and comes into play only in the space complexity analysis. This means that the space bound
(1) Use Theorem 4.2 to determine the optimal partition $S_{1}, S_{2}, \ldots, S_{z}$ of $T^{b w t}$ with respect to $f(t)=K t / \log ^{\varepsilon} t+(1+|\Sigma|) \log n$, where $K$ is larger than the constant hidden in the $O\left(t / \log ^{\varepsilon} t\right)$ term of Theorem 3.2.
(2) Build a binary sequence $\mathcal{B}$ that keeps track of the starting positions in $T^{b w t}$ of the $S_{i}$ 's. The entries of $\mathcal{B}$ are all zeroes, except for the bits at positions $\sum_{j=1}^{i}\left|S_{j}\right|$ for $i=1, \ldots, z$ which are set to 1 . Construct the data structure of Theorem 3.1 (or the one in Raman et al. [2002]) over the binary string $\mathcal{B}$.
(3) For each string $S_{i}, i=1, \ldots, z$ build:
(a) the array $\mathcal{C}_{i}[1,|\Sigma|]$ such that $\mathcal{C}_{i}[c]$ stores the occurrences of character $c$ within $S_{1} S_{2} \cdots S_{i-1}$
(b) the generalized wavelet tree $\mathcal{T}_{i}$ of Theorem 3.2.

FIG. 5. Construction of our improved FM-index.
in Theorem 4.2 holds simultaneously for all $k \geq 0$. The only information required by the booster is the function $f()$ such that $|S| H_{0}(S)+f(|S|)$ is an upper bound on the size of the output produced by $\mathcal{A}$ on input $S$.
4.5. An Improved FM-Index Implementation. We now show how to combine the tools described in previous sections to obtain an FM-index implementation with query time independent of the alphabet size when $|\Sigma|=O(\operatorname{polylog}(n))$. At the end we consider the case of larger alphabets.

The crucial observation is the following. To build the FM-index we need to solve two problems: (a) compress $T^{b w t}$ up to $H_{k}(T)$, and (b) support the efficient computation of $\operatorname{Occ}(c, q)$ and $T^{b w t}[q]$. We use the boosting technique to transform problem (a) into the problem of compressing the strings $S_{1}, S_{2}, \ldots, S_{z}$ up to their zero-order entropy, and use the generalized wavelet tree to create a compressed (up to $H_{0}$ ) and indexable representation of each $S_{i}$, thus solving simultaneously problems (a) and (b).

The details of the construction are given in Figure 5, some comments follow. To compute $T^{b w t}[q]$, we first determine the substring $S_{y}$ containing the $q$ th character of $T^{b \omega t}$ by computing $y=\operatorname{Rank}_{1}(\mathcal{B}, q)$. Then we exploit the generalized wavelet tree $\mathcal{T}_{y}$ to determine $T^{b w t}[q]=S_{y}\left[q^{\prime}\right]$. By Theorem 3.1, the former step takes $O(1)$ time, and by Theorem 3.2 the latter step takes also $O(1)$ time.

To compute $\operatorname{Occ}(c, q)$, we initially determine the substring $S_{y}$ of $T^{b w t}$ where the matrix row $q$ occurs in, $y=\operatorname{Rank}_{1}(\mathcal{B}, q)$. Then we find the relative position of $q$ within $S_{y}$ by calculating $q^{\prime}=q-\sum_{j=1}^{y-1}\left|S_{j}\right|=q-\operatorname{Select}_{1}(\mathcal{B}, y) .^{2}$ Finally, we exploit the generalized wavelet tree $\mathcal{T}_{y}$ and use the array $\mathcal{C}_{y}[c]$ to compute $\operatorname{Occ}(c, q)=\operatorname{Occ}_{S_{y}}\left(c, q^{\prime}\right)+\mathcal{C}_{y}[c]=\operatorname{Rank}_{c}\left(S_{y}, q^{\prime}\right)+\mathcal{C}_{y}[c]$. Again, by Theorems 3.1 and 3.2, this computation takes overall $O(1)$ time. Using this technique inside algorithms count and locate of Section 4.3, we immediately obtain $O(p)$ time to count the occurrences of a pattern $P[1, p]$ and $O\left(\log ^{1+\varepsilon} n\right)$ time to retrieve the position of each occurrence. The time to display a substring of length $\ell$ is $O(\ell)$ in addition to the locate time.

[^1]We now analyze the space occupancy of our data structure. Let us call a sequence $S_{i}$ long if $\left|\Sigma_{i}\right|=O\left(\right.$ polylog$\left.\left(\left|S_{i}\right|\right)\right)$, where $\Sigma_{i}$ is the alphabet of $S_{i}$. Otherwise $S_{i}$ is short.

Let us first assume that all sequences are long. This assumption and Theorem 3.2 allow us to conclude that a generalized wavelet tree $\mathcal{T}_{i}$ built on $S_{i}$ uses $\left|S_{i}\right| H_{0}\left(S_{i}\right)+$ $O\left(\left|S_{i}\right| / \log ^{\varepsilon}\left|S_{i}\right|\right)$ bits for any $0<\varepsilon<1$. By Theorem 3.1, the storage of $\mathcal{B}$ takes $\left\lceil\log \binom{n}{z}\right\rceil+O((n \log \log n) / \log n) \leq z \log n+O((n \log \log n) / \log n)$ bits. Each array $\mathcal{C}_{i}$ takes $|\Sigma| \log n$ bits. Consequently, under the hypothesis that $\left|\Sigma_{i}\right|=$ $O$ (polylog(|Si|)) for all sequences $S_{i}$, the total space occupancy is bounded by

$$
\sum_{i=1}^{z}\left(\left|S_{i}\right| H_{0}\left(S_{i}\right)+K\left|S_{i}\right| / \log ^{\varepsilon}\left|S_{i}\right|+(1+|\Sigma|) \log n\right)+O((n \log \log n) / \log n)
$$

Note that the function $f(t)$ used at step 1 of our construction (see Figure 5) matches exactly the overhead with respect to the $H_{0}$ that we have for each $S_{i}$. From Theorem 4.2 we get that for any $k \geq 0$, we can bound the previous summation by

$$
\begin{equation*}
n H_{k}(T)+O\left(n / \log ^{\varepsilon}\left(n /|\Sigma|^{k}\right)\right)+O\left(|\Sigma|^{k+1} \log n\right)+O((n \log \log n) / \log n) . \tag{5}
\end{equation*}
$$

Recall that we are interested in bounding the space occupancy in terms of $H_{k}(T)$ only for $k \leq \alpha \log _{|\Sigma|} n$ for some $\alpha<1$. In this case we have $|\Sigma|^{k} \leq n^{\alpha}$. By observing that $O((n \log \log n) / \log n)=O\left(n / \log ^{\varepsilon} n\right)$ we turn Eq. (5) into

$$
\begin{equation*}
n H_{k}(T)+O\left(n / \log ^{\varepsilon} n\right) \tag{6}
\end{equation*}
$$

We complete the analysis of the space occupancy by considering the case of short sequences, that is, where $\left|\Sigma_{i}\right|=\omega\left(\right.$ polylog $\left.\left(\left|S_{i}\right|\right)\right)$ for some sequences $S_{i}$. The first part of Theorem 3.2 implies that we can always choose $r=\left|\Sigma_{i}\right|^{1 / \kappa}$ such that all query times are the constant $O\left(\log _{r}\left|\Sigma_{i}\right|\right)=O(\kappa)$. The extra space, however, can only be bounded by $o\left(\left|\Sigma_{i}\right|\left|S_{i}\right|\right)$. Since $\omega\left(\operatorname{polylog}\left(\left|S_{i}\right|\right)\right)=\left|\Sigma_{i}\right| \leq|\Sigma|=$ $O$ (polylog$(n)$ ), we must have $\left|S_{i}\right|=o\left(n^{\beta}\right)$ for any $\beta>0$. Thus, the extra space for a short sequence $S_{i}$ is $o\left(|\Sigma|\left|S_{i}\right|\right)=o\left(n^{\beta} \operatorname{poly} \log (n)\right)$.

Recalling again that we are interested in bounding the space occupancy in terms of $H_{k}(T)$ only for $k \leq \alpha \log _{|\Sigma|} n$ and $\alpha<1$, we have that the overall space overhead because of the (at most $|\Sigma|^{k} \leq n^{\alpha}$ ) short sequences $S_{i}$ is $o\left(n^{\alpha+\beta} \operatorname{poly} \log (n)\right)$ bits for any $\beta>0$. If we take $\beta<1-\alpha$, the space bound becomes $O\left(n / \log ^{\varepsilon} n\right)$ for any desired $0<\varepsilon<1$. Therefore, we can correctly apply Theorem 4.2, since the extra space to represent short sequences can be considered to be the one corresponding to a long sequence plus smaller terms that are left in the sublinear term that accompanies $n H_{k}(T)$.

We note that we have inherited from Eq. (6) a sublinear space cost of the form $O\left(n / \log ^{\varepsilon} n\right)$ for any $0<\varepsilon<1$. Also, from Theorem 4.1, we carry another term of the form $O\left(n / \log ^{\varepsilon} n\right)$ for any $\varepsilon>0$. We then achieve the following result.

THEOREM 4.3. Let $T[1, n]$ be a string over an alphabet $\Sigma$, where $|\Sigma|=$ $O(\operatorname{poly} \log (n))$. The data structure of Figure 5 indexes $T[1, n]$ within $n H_{k}(T)+$ $O\left(n / \log ^{\varepsilon} n\right)$ bits, for any $k \leq \alpha \log _{|\Sigma|} n$ and $0<\alpha, \varepsilon<1$. It can count the number of occurrences of any string $P[1, p]$ in $T$ in $O(p)$ time, locate each occurrence in $O\left(\log ^{1+\varepsilon} n\right)$ time, and display any text substring of length $\ell$ in $O\left(\ell+\log ^{1+\varepsilon} n\right)$ time.
4.5.1. Large Alphabets. Suppose now that the alphabet is larger than $O$ (polylog$(n)$ ), in particular $|\Sigma|=O\left(n^{\beta}\right)$ with $\beta<1$. Corollary 3.3 shows that we can obtain $O(\log |\Sigma| / \log \log n)$ query time on the sequences $S_{i}$, using space $\left|S_{i}\right| H_{0}\left(S_{i}\right)+O\left(|\Sigma| \log \left|S_{i}\right|\right)+o\left(\left|S_{i}\right| \log |\Sigma|\right)$ (more precisely, the latter term is $O\left(\left|S_{i}\right| \log |\Sigma| / \log \log \left|S_{i}\right|\right)$ in Corollary 3.3). It is easy to repeat the analysis and obtain that, instead of Eq. (5), the bound on the size of our index becomes
$n H_{k}(T)+O\left(n \log |\Sigma| / \log \log \left(n /|\Sigma|^{k}\right)\right)+O\left(|\Sigma|^{k+1} \log n\right)+O((n \log \log n) / \log n)$.
Since for any $k \leq \alpha\left(\log _{|\Sigma|} n\right)-1$, with $0<\alpha<1$, the preceding bound is $n H_{k}(T)+o(n \log |\Sigma|)$, we can state the following theorem.

THEOREM 4.4. Let $T[1, n]$ be a string over an alphabet $\Sigma$, with $|\Sigma|=O\left(n^{\beta}\right)$ and $\beta<1$. It is possible to index $T[1, n]$ within $n H_{k}(T)+o(n \log |\Sigma|)$ bits for any $k \leq \alpha\left(\log _{|\Sigma|} n\right)-1$ and $0<\alpha<1$. This index can count the number of occurrences of any string $P[1, p]$ in $T$ in $O(p \log |\Sigma| / \log \log n)$ time, locate each occurrence in $O\left(\log |\Sigma| \log ^{1+\varepsilon} n / \log \log n\right)$ time, and display any text substring of length $\ell$ in $O\left(\left(\ell+\log ^{1+\varepsilon} n\right) \log |\Sigma| / \log \log n\right)$ time .

As an alternative to Theorem 4.4, we can handle large alphabets by decreasing the arity $r$ of our generalized wavelet tree. This reduces the space occupancy of our index at the cost of an increased query time. Here we only discuss the extreme case $r=2$ in which we use the traditional binary wavelet tree instead of our sequence representation. Using binary wavelet trees we can represent each $S_{i}$ in $\left|S_{i}\right| H_{0}\left(S_{i}\right)+O\left(\log |\Sigma|\left(\left|S_{i}\right| \log \log \left|S_{i}\right|\right) / \log \left|S_{i}\right|\right)$ bits of storage. Combining this representation with the compression booster we get an index of size bounded by $n H_{k}(T)+O(\log |\Sigma|(n \log \log n / \log n))$ bits for any $k \leq\left(\alpha \log _{|\Sigma|} n\right)-1$ and $\alpha<1$. Since querying a binary wavelet tree takes $O(\log |\Sigma|)$ time, our simplified index can count the number of occurrences in $O(p \log |\Sigma|)$ time, locate each occurrence in $O\left(\log |\Sigma|\left(\log ^{2} n / \log \log n\right)\right.$ ), and display any text substring of length $\ell$ in $\left.O\left(\log |\Sigma|\left(\ell+\log ^{2} n\right) / \log \log n\right)\right)$ time. The details on the analysis of the preceding simplified index can be found in Ferragina et al. [2004].

## 5. Conclusions

The contribution of this article is twofold. First, we have presented a compressed representation of sequences $S[1, n]$ that requires $n H_{0}(S)+o(n)$ bits of space and is able to retrieve individual symbols $S[q]$ and answer rank and select queries in constant time. The technique works whenever the alphabet size of the sequence satisfies the condition $|\Sigma|=O($ polylog$(n))$. This is a nontrivial generalization of previous results on binary sequences [Raman et al. 2002] and an improvement of previous results on general sequences [Grossi et al. 2003].

Secondly, we have combined the aforementioned result with an existing compression boosting technique to obtain a compressed full-text index for a text $T[1, n]$, which uses $n H_{k}(T)+o(n)$ bits whenever the alphabet size is $O(\operatorname{poly} \log (n))$. Our index has the smallest-known space occupancy, is a self-index, is faster than other indexes of the same size, and the first compressed index with query time independent of alphabet size. We have also shown that on larger alphabets we can still improve the best existing results.

After the first publication of this article, some new techniques have been proposed that enable improving our bounds on rank and select queries slightly: Golynski et al. [2006] propose a succinct structure that supports rank in $O(\log \log \sigma)$ time and select in constant time. Their structure is, however, not compressed, as it uses $n \log \sigma+o(n \log \sigma)$ bits. Hence, it cannot be coupled with the compression boosting technique. Sadakane and Grossi [2006] propose a technique to represent a sequence $X$ in $n H_{k}(X)+o(n \log |\Sigma|)$ bits supporting constant access to its short substrings. However, even using this more powerful representation, compression boosting still appears necessary to achieve a space usage bounded by $n H_{k}(T)+o(n)$ bits (see González and Navarro [2006]).

There are several future challenges on compressed full-text indexes: (i) obtaining better results when the alphabet size is not $O$ (polylog$(n)$ ); (ii) removing the limit on the maximum entropy order $k$ that can be achieved, which is currently $k \leq \alpha \log _{|\Sigma|} n$ for any $0<\alpha<1$; (iii) achieving optimal query times within $n H_{k}(T)+o(n)$ space, that is, $O\left(p / \log _{|\Sigma|} n\right)$ for counting and $O(1)$ for locating, as opposed to our $O(p)$ and $O\left(\log ^{1+\varepsilon} n\right)$ (this has been partially achieved [Grossi and Vitter 2006; Ferragina and Manzini 2005] in some cases); (iv) coping with updates to the text and secondary memory issues (see e.g. Ferragina and Manzini [2005], Chan et al. [2004], and Hon et al. [2004]); (v) handling more sophisticated searching, such as approximate and regular expression searching (see e.g. Huynh et al. [2004]).

It should be clear, however, that some limits cannot be surpassed. For example, one cannot achieve an $n H_{k}(T)+o(n)$ space bound without any restriction on $|\Sigma|$ or $k$. To see this, consider the extreme case in which $|\Sigma|=n$, that is, the input string consists of a permutation of $n$ distinct characters. In this case we have $H_{k}(T)=0$ for all $k \geq 1$, and any representation of such a string must require $\Omega(n \log n)$ bits. Hence a self-index of size $n H_{k}(T)+o(n)$ bits cannot exist. Understanding which are the limits and the space-time tradeoffs that can be achieved on compressible strings (compare with Demaine and López-Ortiz [2003]) is an extremely interesting open problem.

RECEIVED NOVEMBER 2004; ACCEPTED JANUARY 2006

[^0]:    ${ }^{1}$ In the binary case $(r=2), R_{i}$ is just the number of bits set in $S_{i}$ [Raman et al. 2002], but this is more complicated here.

[^1]:    ${ }^{2}$ Instead of implementing select we can just store all these partial sums at $O(z \log n)$ extra space, where $z$ is the number of pieces in the $T^{b w t}$ partition, and this cost does not affect the overall space result.
